(Draft January 30, 2015)

We report the results of a joint analysis of data from BICEP2/*Keck Array* and *Planck*. BICEP2 and *Keck Array* have observed the same approximately 400 deg² patch of sky centered on RA 0h, Dec. -57.5° . The combined maps reach a depth of 57 nK deg in Stokes Q and U in a band centered at 150 GHz. *Planck* has observed the full sky in polarization at seven frequencies from 30 to 353 GHz, but much less deeply in any given region (1.2 μ K deg in Q and U at 143 GHz). We detect 150×353 cross-correlation in B -modes at high significance. We fit the single- and cross-frequency power spectra at frequencies above 150 GHz to a lensed- Λ CDM model that includes dust and a possible contribution from inflationary gravitational waves (as parameterized by the tensor-to-scalar ratio r). We probe various model variations and extensions, including adding a synchrotron component in combination with lower frequency data, and find that these make little difference to the r constraint. Finally we present an alternative analysis which is similar to a map-based cleaning of the dust contribution, and show that this gives similar constraints. The final result is expressed as a likelihood curve for r , and yields an upper limit $r_{0.05} < 0.12$ at 95% confidence. Marginalizing over dust and r , lensing B -modes are detected at 7.0σ significance.

PACS numbers: 98.70.Vc, 04.80.Nn, 95.85.Bh, 98.80.Es

I. INTRODUCTION

The cosmic microwave background (CMB) [1], is an essential source of information about all epochs of the Universe. In the past several decades, characterization of the temperature and polarization anisotropies of the CMB has helped to establish the standard cosmological model (Λ CDM) and to measure its parameters to high precision (see for example Refs. [2, 3]).

An extension to the standard big bang model, inflation, postulates a short period of exponential expansion in the very early Universe, naturally setting the initial conditions required by Λ CDM, as well as solving a number of additional problems in standard cosmology. Inflation's basic predictions regarding the Universe's large-scale geometry and structure have been borne out by cosmological measurements to date (see Ref. [4] for a review). Inflation makes an additional prediction, the existence of a background of gravitational waves, or tensor mode perturbations [5–8]. At the recombination epoch, the inflationary gravitational waves (IGW) contribute to the anisotropy of the CMB in both total intensity and linear polarization. The amplitude of tensors is conventionally parameterized by r , the tensor-to-scalar ratio at a fiducial scale. Theoretical predictions of the value of r cover a very wide range. Conversely, a measurement of r can discriminate between models of inflation.

Tensor modes produce a small increment in the temperature anisotropy power spectrum over the standard Λ CDM scalar perturbations at multipoles $\ell \lesssim 60$; mea-

suring this increment requires the large sky coverage traditionally achieved by space-based experiments, and an understanding of the other cosmological parameters. The effects of tensor perturbations on B -mode polarization is less ambiguous than on temperature or E -mode polarization over the range $\ell \lesssim 150$. The B -mode polarization signal produced by scalar perturbations is very small and is dominated by the weak lensing of E -mode polarization on small angular scales, making the detection of an IGW contribution possible [9–12].

Planck [13] was the third generation CMB space mission, which mapped the full sky in polarization in seven bands centered at frequencies from 30 GHz to 353 GHz to a resolution of 33 to 5 arcminutes [14, 15]. The *Planck* collaboration has published the best limit to date on tensor modes using CMB data alone [3]: $r_{0.002} < 0.11$ (at 95% confidence) using a combination of *Planck*, SPT and ACT temperature data, plus WMAP polarization, although the *Planck* r limit is model-dependent, with running of the scalar spectral index or additional relativistic degrees of freedom being well-known degeneracies which allow larger values of r .

Interstellar dust grains produce thermal emission, the brightness of which increases rapidly from the 100–150 GHz frequencies favored for CMB observations, becoming dominant at ≥ 350 GHz even at high galactic latitude. The dust grains align with the Galactic magnetic field to produce emission with a degree of linear polarization [16]. The observed degree of polarization depends on the structure of the Galactic magnetic field along the line

of sight, as well as the properties of the dust grains (see for example Refs. [17, 18]). This polarized dust emission results in both E -mode and B -mode, and acts as a potential contaminant to a measurement of r . Galactic dust polarization was detected by Archeops [19] at 353 GHz and by WMAP [2, 20] at 90 GHz.

BICEP2 was a specialized, low angular resolution experiment, which operated from the South Pole from 2010 to 2012, concentrating 150 GHz sensitivity comparable to *Planck* on a roughly 1% patch of sky at high Galactic latitude [21]. The BICEP2 Collaboration published a highly significant detection of B -mode polarization in excess of the $r=0$ lensed- Λ CDM expectation over the range $30 < \ell < 150$ in Ref. [22, hereafter BK-I]. Modest evidence against a thermal Galactic dust component dominating the observed signal was presented based on the cross-spectrum against 100 GHz maps from the previous BICEP1 experiment. The detected B -mode level was higher than that projected by several existing dust models [23, 24] although these did not claim any high degree of reliability.

The *Planck* survey released information on the structure of the dust polarization sky at intermediate latitudes [25], and the frequency dependence of the polarized dust emission at frequencies relevant to CMB studies [26]. Other papers argued that the BICEP2 region is significantly contaminated by dust [27, 28]. Finally *Planck* released information on dust polarization at high latitude [29, hereafter PIP-XXX], and in particular examined a field centered on the BICEP2 region (but somewhat larger than it) finding a level of polarized dust emission at 353 GHz sufficient to explain the 150 GHz excess observed by BICEP2, although with relatively low signal-to-noise.

Keck Array is a system of BICEP2-like receivers also located at the South Pole. During the 2012 and 2013 seasons *Keck Array* observed the same field as BICEP2 in the same 150 GHz frequency band [30, hereafter BK-V]. Combining the BICEP2 and *Keck Array* maps yields Q and U maps with rms noise of 57 nK in nominal 1 deg^2 pixels—by far the deepest made to date.

In this paper, we take cross-spectra between the joint BICEP2/*Keck* maps and all the polarized bands of *Planck*. The structure is as follows. In Sec. II we describe the preparation of the input maps, the expectations for dust, and the power spectrum results. In Sec. III the main multi-frequency cross-spectrum likelihood method is introduced and applied to the data, and a number of variations from the selected fiducial analysis are explored. Sec. IV describes validation tests using simulations as well as an alternate likelihood. In Sec. V we investigate whether there could be decorrelation between the *Planck* and BICEP2/*Keck* maps due to the astrophysics of dust and/or instrumental effects. Finally we conclude in Sec. VI.

II. MAPS TO POWER SPECTRA

A. Maps and preparation

We primarily use the BICEP2/*Keck* combined maps, as described in BK-V. We also use the BICEP2-only and *Keck*-only maps as a cross check. The *Planck* maps used for cross-correlation with BICEP2/*Keck* are the full-mission polarized maps from the PR2 *Planck* science release [31] [32], a subset of which was presented in PIP-XXX. We compute *Planck* single-frequency spectra by taking crosses between data-split maps; we consider detector-set maps, yearly maps, and half-ring maps [33]. To evaluate uncertainties due to *Planck* instrumental noise, we use 500 noise simulations of each map; these are the standard set of time-ordered data noise simulations projected into sky maps (the FFP8 simulations defined in Ref. [34]).

While the *Planck* maps are filtered only by the instrument beam (the effective beam defined in Refs. [35] and [36]), the BICEP2/*Keck* maps are in addition filtered due to the observation strategy and analysis process. In particular, large angular scales are suppressed anisotropically in the BICEP2/*Keck* mapmaking process to avoid atmospheric and ground-fixed contamination; this suppression is corrected in the power spectrum estimate. In order to facilitate comparison, we therefore prepare “*Planck* as seen by BICEP2/*Keck*” maps. In the first step we use the ANAFast, ALTERALM and SYNFAST routines from the HEALPix [37] package [38] to resmooth the *Planck* maps with the BICEP2/*Keck* beam profile, assuming azimuthal symmetry of the beam. The coordinate rotation from Galactic to celestial coordinates of the T , Q , and U maps is performed using the ALTERALM routine in the HEALPix package. The sign of the Stokes U map is flipped to convert from the HEALPix to the IAU polarization convention. Next we pass these through the “observing” matrix R , described in Section VI.B of BK-I, to produce maps that include the filtering of modes occurring in the data processing pipeline (including polynomial filtering and scan-synchronous template removal, plus deprojection of beam systematics).

Figure 1 shows the resmoothed *Planck* 353 GHz T , Q , and U maps before and after filtering. In both cases the BICEP2/*Keck* inverse variance apodization mask has been applied. This figure emphasizes the need to account for the filtering before any comparison of maps is attempted, either qualitative or quantitative.

B. Expected spatial and frequency spectra of dust

Before examining the power spectra it is useful to review expectations for the spatial and frequency spectra of dust. Figure 2 of PIP-XXX shows that the dust BB (and EE) angular power spectra are well fit by a simple power law $\mathcal{D}_\ell \propto \ell^{-0.42}$, where $\mathcal{D}_\ell = C_\ell \ell(\ell + 1)/2\pi$, when averaging over large regions of sky. Section 5.2 of

FIG. 1. *Planck* 353 GHz T , Q , and U maps before (left) and after (right) the application of BICEP2/*Keck* filtering. In both cases the maps have been multiplied by the BICEP2/*Keck* apodization mask. The *Planck* maps are presmoothed to the BICEP2/*Keck* beam profile and have the mean value subtracted. The filtering, in particular the third order polynomial subtraction to suppress atmospheric pickup, removes large-angular scale signal along the BICEP2/*Keck* scanning direction (parallel to the right ascension direction in the maps here).

the same paper states that there is no evidence for departure from this behavior for 1% sky patches, although the signal-to-noise ratio is low for some regions. Presumably we expect greater fluctuation from the mean behavior than would be expected for a Gaussian random field.

The spectral energy distribution (SED) of dust polarization was measured in Ref. [26] for 400 patches with 10° radius at intermediate Galactic latitudes. The SED is well fit by a modified blackbody spectrum with $T_d = 19.6$ K and $\beta_d = 1.59 \pm 0.17$, where the dust temperature is obtained from a fit to the SED of total intensity, and the uncertainty on the spectral index represents the 1σ dispersion of the individual patch measurements. The uncertainty is an upper limit, since some fluctuation is due to noise rather than real variation on the sky. This SED is confirmed to be a good match to data when averaging over 24% of the cleanest high latitude sky in Fig. 6 of PIP-XXX.

C. Power spectrum estimation and results

The power spectrum estimation proceeds exactly as in BK-I, including the matrix based purification operation to prevent E to B mixing. Figure 2 shows the results for BICEP2/*Keck* and *Planck* 353 GHz for TT , TE , EE , and BB . In all cases the error bars are the standard deviations of lensed- Λ CDM+noise simulations [39] and hence contain no sample variance on any other component. The results in the left column are auto-spectra, identical to those given in BK-I and BK-V—these spectra are consistent with lensed- Λ CDM+noise except for the excess in BB for $\ell < 200$.

The right column of Fig. 2 shows cross-spectra between two halves of the *Planck* 353 GHz data set, with three different splits shown. The *Planck* collaboration prefers the use of cross-spectra even at a single frequency to gain additional immunity to systematics and to avoid the need to noise debias auto-spectra. The TT spectrum is higher than Λ CDM around $\ell = 200$ —presumably due to a dust

FIG. 2. Single- and cross-frequency spectra between BICEP2/Keck maps at 150 GHz and *Planck* maps at 353 GHz. The left column shows single-frequency spectra of the BICEP2, Keck Array and combined BICEP2/Keck maps. The BICEP2 spectra are identical to those in BK-I, while the Keck Array and combined are as given in BK-V. The center column shows cross-frequency spectra between BICEP2/Keck maps and *Planck* 353 GHz maps. The right column shows *Planck* 353 GHz data-split cross-spectra. In all cases the error bars are the standard deviations of lensed- Λ CDM+noise simulations and hence contain no sample variance on any other component. For EE and BB the χ^2 and χ (sum of deviations) versus lensed- Λ CDM for the nine bandpowers shown is marked at upper/lower left (for the combined BICEP2/Keck points and DS1 \times DS2). In the bottom row (for BB) the center and right panels have a scaling applied such that signal from dust with the fiducial frequency spectrum would produce signal with the same apparent amplitude as in the 150 GHz panel on the left (as indicated by the right-side y -axes). We see from the significant excess apparent in the bottom center panel that a substantial amount of the signal detected at 150 GHz by BICEP2 and Keck Array indeed appears to be due to dust.

contribution. The EE and BB spectra are noisy, but both appear to show an excess over Λ CDM for $\ell < 150$ —again presumably due to dust. We note that these spectra do not appear to follow the power-law expectation mentioned in Sec. II B, but we emphasize that the error bars contain no sample variance on any dust component (Gaussian or otherwise).

The center column of Fig. 2 shows cross-spectra between BICEP2/Keck and *Planck* maps. For TE one can use the T -modes from BICEP2 and the E -modes from *Planck* or vice versa and both options are shown.

Since the T -modes are very similar between the two experiments, these TE spectra look similar to the single-experiment TE spectrum which shares the E -modes. The EE and BB cross-spectra are the most interesting—there appears to be a highly significant detection of correlated B -mode power between 150 and 353 GHz, with the pattern being much brighter at 353, consistent with the expectation from dust. We also see hints of detection in the EE spectrum—while dust E -modes are subdominant to the cosmological signal at 150 GHz, the weak dust contribution enhances the BK150 \times P353 cross-spectrum

at $\ell \approx 100$.

The polarized dust SED model mentioned in Sec. II B implies that dust emission is approximately 25 times brighter in the *Planck* 353 GHz band than it is in the BICEP2/*Keck* 150 GHz band (integrating appropriately over the instrumental bandpasses). The expectation for a dust-dominated spectrum is thus that the BK150×P353 cross-spectrum should have an amplitude 25 times that of BK150×BK150, and P353×P353 should be 25 times higher again. The y -axis scaling in the bottom row of Fig. 2 has been adjusted so that a dust signal obeying this rule will have equal apparent amplitude in each panel. We see that a substantial amount of the BK150×BK150 signal indeed appears to be due to dust.

To make a rough estimate of the significance of deviation from lensed- Λ CDM, we calculate χ^2 and χ (sum of deviations) for each of the EE and BB spectra and show these in Fig. 2. For the nine bandpowers used the expectation value/standard-deviation for χ^2 and χ are 9/4.2 and 0/3 respectively. We see that BK150×BK150 and BK150×P353 are highly significant in BB , while P353×P353 has modest significance in both EE and BB .

Figure 3 shows EE and BB cross-spectra between BICEP2/*Keck* and all of the polarized frequencies of *Planck* (also including the BICEP2/*Keck* auto-spectra). For the five bandpowers shown the expectation value/standard-deviation for χ^2 and χ are 5/3.1 and 0/2.2 respectively. As already noted, the BK150×BK150 and BK150×P353 BB spectra show highly significant excesses. Additionally, there is evidence for excess BB in BK150×P217 spectrum, and for excess EE in BK150×P353. The other spectra in Fig. 3 show no strong evidence for excess, although we note that only one of the χ values is negative. There is weak evidence for excess in the BK150×P70 BB spectrum but none in BK150×P30 so this is presumably just a noise fluctuation.

There are a large number of additional *Planck*-only spectra, which are not plotted here. The noise on these is large and all are consistent with Λ CDM, with the possible exception of P217×P353, where modest evidence for an excess is seen in both EE and BB (see e.g., Figure 10 of PIP-XXX).

D. Consistency of BICEP2 and *Keck* Array spectra

The BB auto-spectra for BICEP2 and *Keck* Array in the lower left panel of Fig. 2 appear to differ by more than might be expected, given that the BICEP2 and *Keck* maps cover almost exactly the same region of sky. However, the error bars in this figure are the standard deviations of lensed- Λ CDM+noise simulations; while the signal is largely common between the two experiments the noise is not, and the signal-noise cross terms produce substantial additional fluctuation of the difference. The correct way to quantify this is to compare the difference of the real data to the pair-wise differences of simulations, using common input skies that have power similar to that

FIG. 3. EE (left column) and BB (right column) cross-spectra between BICEP2/*Keck* maps and all of the polarized frequencies of *Planck*. In all cases the quantity plotted is $\ell(\ell+1)C_l/2\pi$ in units of $\mu\text{K}_{\text{CMB}}^2$. The error bars are the standard deviations of lensed- Λ CDM+noise simulations and hence contain no sample variance on any other component. Also note that the y -axis scales differ from panel to panel in the right column. The χ^2 and χ (sum of deviations) versus lensed- Λ CDM for the five bandpowers shown is marked at upper left. There are no additional strong detections of deviation from lensed- Λ CDM over those already shown in Fig. 2 although BK150×P217 shows some evidence of excess.

FIG. 4. Differences of B150×P353 and K150×P353 BB cross-spectra. The error bars are the standard deviations of the pairwise differences of signal+noise simulations that share common input skies. The probability to exceed the observed values of χ^2 and χ statistics, as evaluated against the simulations, is quoted for bandpower ranges 1–5 ($20 < \ell < 200$) and 1–9 ($20 < \ell < 330$). There is no evidence that these spectra are statistically incompatible.

observed in the real data. This was done in Section 8 of BK-V and the BICEP2 and *Keck* maps were shown to be statistically compatible. In an analogous manner we can also ask if the B150×P353 and K150×P353 BB cross-spectra shown in the bottom middle panel of Fig. 2 are compatible. Figure 4 shows the results. We calculate the χ^2 and χ statistics on these difference spectra and compare to the simulated distributions exactly as in BK-V. The probability to exceed (PTE) the observed values is given in the figure for bandpowers 1–5 ($20 < \ell < 200$) and 1–9 ($20 < \ell < 330$). There is no evidence that these spectra are statistically incompatible.

E. Alternative power spectrum estimation

We check the reliability of the power spectrum estimation with an alternative pipeline. The filtered and purified *Planck* and BICEP2 maps used to make the spectra shown in Fig. 2 are transformed back into the HEALPix pixelization using cubic spline interpolation. The B -mode cross-power is then computed with the XPOL [40] and PURECL [41] estimators. Figure 5 shows the difference between these alternative bandpowers and the standard bandpowers for the B150×P353 BB cross spectrum. As in Fig. 4 the errorbars are the standard deviations of pairwise differences of simulations, which share common input skies and have power similar to that observed in the real data. The agreement is not expected to be exact due to the differing bandpower window functions, but the differences of the real bandpowers are consistent with those of the simulations.

FIG. 5. Differences of B150×P353 BB cross-spectra from the standard power spectrum estimator and alternate estimators. The error bars are the standard deviations of the pairwise differences of signal+noise simulations that share common input skies. We see that the differences of the real spectra are consistent with the differences of the simulations.

III. LIKELIHOOD ANALYSIS

A. Algorithm

While it is conventional in plots like Fig. 2 to present bandpowers with symmetric error bars, it is important to appreciate that this is an approximation. The likelihood of an observed bandpower for a given model expectation value is generally an asymmetric function, which can be computed given knowledge of the noise level(s). To compute the joint likelihood of an ensemble of measured bandpower values it is of course necessary to consider their full covariance—this is especially important when using spectra taken at different frequencies on the same field, where the signal covariance can be very strong.

We compute the bandpower covariance using full simulations of signal-cross-signal, noise-cross-noise, and signal-cross-noise. From these, we can construct the covariance matrix for a general model containing multiple signal components with any desired set of SEDs. When we do this we deliberately exclude terms whose expectation value is zero, in order to reduce noise in the resulting matrix due to the limited number of simulated realizations.

To compute the joint likelihood of the data for any given proposed model we use the Hamimeche-Lewis [42] approximation (HL; see Section 9.1 of Ref. [43] for implementation details). Here we extend the method to deal with single- and cross-frequency spectra, and the covariances thereof, in an analogous manner to the treatment of, for example, TT , TE , and EE in the standard HL method. The HL formulation requires that the bandpower covariance matrix be determined for only a single “fiducial model.” We compute multi-dimensional grids of models explicitly and/or use COSMOMC [44] to sample

the parameter space.

B. Fiducial analysis

As an extension of the simplest lensed- Λ CDM paradigm, we initially consider a two component model of IGW with amplitude r , plus dust with amplitude A_d (specified at 353 GHz and $\ell = 80$). (Here we assume that the spectral index of the tensor modes (n_t) is zero, and a scalar pivot scale of 0.05 Mpc^{-1} ; all values of r quoted in this paper are $r_{0.05}$ unless noted otherwise.) Figure 6 shows the results of fitting such a model to BB bandpowers taken between BICEP2/*Keck* and the 217 and 353 GHz bands of *Planck*, using bandpowers 1–5 ($20 < \ell < 200$). For the *Planck* single-frequency case, the cross-spectrum of detector-sets (DS1 \times DS2) is used, following PIP-XXX. The dust is modeled as a power law $D_\ell \propto \ell^{-0.42}$, with free amplitude A_d and scaling with frequency according to the modified blackbody model.

A tight Gaussian prior $\beta_d = 1.59 \pm 0.11$ is imposed, since this parameter is not well constrained from these data alone, but does appear to be stable across the sky (see Secs. II B and V A). For the frequency range of interest here variations in the two parameters of the modified blackbody are highly degenerate and the choice is made to hold T_d fixed while allowing β_d to be free. The prior assumes that the SED of dust polarization at intermediate latitudes [26] applies to the BICEP2/*Keck* field, where the signal-to-noise ratio of the *Planck* data is too low to determine it directly. From dust astrophysics, we expect variations of the dust SED in intensity and polarization to be correlated [18]. We thus tested our assumption by measuring the spectral index of the dust total intensity in the BICEP2/*Keck* field using the template fitting analysis described in Ref. [45], and find the same value. The uncertainty on β_d is scaled from the dispersion of spectral indices at intermediate Galactic latitudes in Ref. [26], as explained in PIP-XXX.

In Fig. 6 we see that the BICEP2 data produce an r likelihood that peaks higher than that for the *Keck Array* data. This is because for $\ell < 120$ the auto-spectrum B150 \times B150 is higher than for K150 \times K150, while the cross-spectrum B150 \times P353 is lower than K150 \times P353 (see Fig. 2). However, recall that both pairs of spectra B150 \times B150/K150 \times K150 and B150 \times P353/K150 \times P353 have been shown to be consistent within noise fluctuation (see Sec. II D). In Sec. IV A these likelihood results are also found to be compatible. Given the consistency between the two experiments, the combined result gives the best available measurement of the sky.

The combined curves (BK+P) in the left and center panels of Fig. 6 yield the following results: $r = 0.048_{-0.032}^{+0.035}$, $r < 0.12$ at 95% confidence, and $A_d = 3.3_{-0.8}^{+0.9}$. For r the zero-to-peak likelihood ratio is 0.38. Taking $\frac{1}{2}(1 - f(-2 \log L_0/L_{\text{peak}}))$, where f is the χ^2 cdf (for one degree of freedom), we estimate that the probability to get a number smaller than this is 8% if in fact

$r = 0$. For A_d the zero-to-peak ratio is 1.8×10^{-6} corresponding to a smaller-than probability of 1.4×10^{-7} , and a 5.1σ detection of dust power.

The maximum likelihood model on the grid has parameters $r = 0.05$, $A_d = 3.30 \mu\text{K}^2$ (and $\beta_d = 1.6$). Computing the bandpower covariance matrix for this model, we obtain a χ^2 of 40.9. Using 28 degrees of freedom—5 bandpowers times 6 spectra, minus 2 fit parameters (since β_d is not really free)—gives a PTE of 0.06. The largest contributions to χ^2 come from the P353 \times P353 spectrum shown in the lower right panel of Fig. 2.

C. Variations from the fiducial data set and model

We now investigate a number of variations from the fiducial analysis to see what difference these make to the constraint on r .

- **Choice of *Planck* single-frequency spectra:** switching the *Planck* single-frequency spectra to use one of the alternative data splits (yearly or half-year instead of detector-set) makes little difference (see Fig. 7).
- **Using only 150 and 353 GHz:** dropping the spectra involving 217 GHz from consideration also has little effect (see Fig. 7).
- **Using only BK150 \times BK150 and BK150 \times P353:** also excluding the 353 GHz single-frequency spectrum from consideration makes little difference. The statistical weight of the BK150 \times BK150 and BK150 \times P353 spectra dominate (see Fig. 7).
- **Extending the bandpower range:** going back to the base data set and extending the range of bandpowers considered to 1–9 (corresponding to $20 < \ell < 330$) makes very little difference—the dominant statistical weight is with the lower bandpowers (see Fig. 7).
- **Including EE spectra:** we can also include in the fits the EE spectra shown in Fig. 3. PIP-XXX (figures 5 and A.3) shows that the level of EE from Galactic dust is on average around twice the level of BB . However, there are substantial variations in this ratio from sky-patch to sky-patch. Setting $EE/BB = 2$ we find that the constraint on A_d narrows, while the r constraint changes little; this latter result is also shown in Fig. 7.
- **Relaxing the β_d prior:** relaxing the prior on the dust spectral index to $\beta_d = 1.59 \pm 0.33$ pushes the peak of the r constraint up (see Fig. 7). However, it is not clear if this looser prior is self consistent; if the frequency spectral index varied significantly across the sky it would invalidate cross-spectral analysis, but there is strong evidence against such

FIG. 6. Likelihood results from a basic lensed- Λ CDM+ r +dust model, fitting BB auto- and cross-spectra taken between maps at 150 GHz, 217, and 353 GHz. The 217 and 353 GHz maps come from *Planck*. The primary results (heavy black) use the 150 GHz combined maps from BICEP2/*Keck*. Alternate curves (light blue and red) show how the results vary when the BICEP2 and *Keck Array* only maps are used. In all cases a Gaussian prior is placed on the dust frequency spectrum parameter $\beta_d = 1.59 \pm 0.11$. In the right panel the two dimensional contours enclose 68% and 95% of the total likelihood.

variation at high latitude, as explained in Sec. V A. Nevertheless, it is important to appreciate that the r constraint curves shown in Fig. 6 shift left (right) when assuming a lower (higher) value of β_d . For $\beta_d = 1.3 \pm 0.11$ the peak is at $r = 0.021$ and for $\beta_d = 1.9 \pm 0.11$ the peak is at $r = 0.073$.

- Varying the dust power spectrum shape:** in the fiducial analysis the dust spatial power spectrum is assumed to be a power law with $\mathcal{D}_\ell \propto \ell^{-0.42}$. Marginalizing over spectral indices in the range -0.8 to 0 we find little change in the r constraint (see also Sec. IV B for an alternate relaxation of the assumptions regarding the spatial properties of the dust pattern).
- Using Gaussian determinant likelihood:** the fiducial analysis uses the HL likelihood approximation, as described in Sec. III A. An alternative is to recompute the covariance matrix \mathbf{C} at each point in parameter space and take $L = \det(\mathbf{C})^{-1/2} \exp(-(\mathbf{d}^T \mathbf{C}^{-1} \mathbf{d})/2)$, where \mathbf{d} is the deviation of the observed bandpowers from the model expectation values. This results in an r constraint which peaks slightly lower, as shown in Fig. 7. Running both methods on the simulated realizations described in Sec. IV A, indicates that such a difference is not unexpected and that there may be a small systematic downward bias in the Gaussian determinant method.
- Varying the HL fiducial model:** as mentioned in Sec. III A the HL likelihood formulation requires that the expectation values and bandpower covariance matrix be provided for a single “fiducial model” (not to be confused with the “fiducial analysis” of Sec. III B). Normally we use the lensed- Λ CDM+dust simulations described in Sec. IV A below. Switching this to lensed- Λ CDM+ $r=0.2$ produces no change on average in the simulations, al-

though it does cause any given realization to shift slightly—the change for the real data case is shown in Fig. 7.

- Adding synchrotron:** BK-I took the WMAP K -band (23 GHz) map, extrapolated it to 150 GHz according to $\nu^{-3.3}$ (mean value within the BICEP2 field of the MCMC “Model f” spectral index map provided by WMAP [2]), and found a negligible predicted contribution ($r_{\text{sync},150} = 0.0008 \pm 0.0041$). Figure 3 does not offer strong motivation to reexamine this finding—the only significant detections of correlated BB power are in the BK150 \times P353 and, to a lesser extent, BK150 \times P217 spectra. However, here we proceed to a fit including all the polarized bands of *Planck* (as shown in Fig. 3) and adding a synchrotron component to the base lensed- Λ CDM+noise+ r +dust model. We take synchrotron to have a power law spectrum $\mathcal{D}_\ell \propto \ell^{-0.6}$ [23], with free amplitude A_{sync} , where A_{sync} is the amplitude at $\ell = 80$ and at 150 GHz, and scaling with frequency according to $\nu^{-3.3}$. In such a scenario we can vary the degree of correlation that is assumed between the dust and synchrotron sky patterns. Figure 8 shows results for the uncorrelated and fully correlated cases. Marginalizing over r and A_d we find $A_{\text{sync}} < 0.0003 \mu\text{K}^2$ at 95% confidence for the uncorrelated case, and many times smaller for the correlated. This last is because once one has a detection of dust it effectively becomes a template for the synchrotron. This synchrotron limit is driven by the *Planck* 30 GHz band—we obtain almost identical results when adding only this band, and a much softer limit when not including it. If we instead assume synchrotron scaling of $\nu^{-3.0}$ the limit on A_{sync} is approximately doubled for the uncorrelated case and reduced for the correlated. (Because the DS1 \times DS2 data-split is not available for the *Planck* LFI bands we switch to Y1 \times Y2 for

FIG. 7. Likelihood results when varying the data sets used and the model priors—see Sec III C for details.

this variant analysis, and so we compare to this case in Fig. 8 rather than the usual fiducial case.)

- Varying lensing amplitude:** in the fiducial analysis the amplitude of the lensing effect is held fixed at the Λ CDM expectation ($A_L = 1$). Using their own and other data, the *Planck* Collaboration quote a limit on the amplitude of the lensing effect versus the Λ CDM expectation of $A_L = 0.99 \pm 0.05$ [3]. Allowing A_L to float freely, and using all nine bandpowers, we obtain the results shown in Fig. 9—there is only weak degeneracy between A_L and both r and A_d . Marginalizing over r and A_d we find $A_L = 1.13 \pm 0.18$ with a likelihood ratio between zero and peak of 3×10^{-11} . Using the expression given in Sec. III B this corresponds to a smaller-than probability of 2×10^{-12} , equivalent to a 7.0σ detection of lensing in the BB spectrum. We note this is the most significant to-date direct measurement of lensing in B -mode polarization.

IV. LIKELIHOOD VALIDATION

A. Validation with simulations

We run the algorithm used in Sec. III B on ensembles of simulated realizations to check its performance. We first consider a model where $r = 0$ and $A_d = 3.6 \mu\text{K}^2$, this latter being close to the value favored by the data in a dust-only scenario [46]. We generate Gaussian random realizations using the fiducial spatial power law $\mathcal{D}_\ell \propto \ell^{-0.42}$, scale these to the various frequency bands using the modified blackbody law with $T_d = 19.6 \text{ K}$ and $\beta_d = 1.59$, and add to the usual realizations of lensed- Λ CDM+noise. Figure 10 shows the resulting r and A_d constraint curves, with the result for the real data from Fig. 6 overplotted. As expected, approximately 50% of the r likelihoods peak

FIG. 8. Likelihood results for a fit when adding the lower frequency bands of *Planck*, and extending the model to include a synchrotron component. The results for two different assumed degrees of correlation between the dust and synchrotron sky patterns are compared to those for the comparable model without synchrotron (see text for details).

FIG. 9. Likelihood results for a fit allowing the lensing scale factor A_L to float freely and using all nine bandpowers. Marginalizing over r and A_d , we find that $A_L = 1.13 \pm 0.18$ and $A_L = 0$ is ruled out with 7.0σ significance.

above zero. The median 95% upper limit is $r < 0.075$. We find that 8% of the realizations have a ratio L_0/L_{peak} less than the 0.38 observed in the real data, in agreement with the estimate in Sec. III B. Running these dust-only realizations for BICEP2 only and *Keck Array* only, we find that the shift in the maximum likelihood value of r seen in the real data in Fig. 6 is exceeded in about 10% of the simulations.

The above simulations assume that the dust component follows on average the fiducial $\mathcal{D}_\ell \propto \ell^{-0.42}$ spatial power law, and fluctuates around it in a Gaussian manner. To obtain sample dust sky patterns that may deviate from this behavior in a way which better reflects reality, we take the pre-launch version of the *Planck* Sky Model (PSM; version 1.7.8 run in “simulation” mode) [24] evaluated in the *Planck* 353 GHz band and pull out the same 352 $|b| > 35^\circ$ partially overlapping regions used in PIP-XXX. We then scale these to the other bands and proceed as before. Figure 11 presents the results. Some of the regions have dust power orders of magnitude higher than the real data and we cut them out (selecting 139 regions with peak $A_d < 20 \mu\text{K}^2$). The r likelihoods will broaden

FIG. 10. Likelihoods for r and A_d , using BICEP2/*Keck* and *Planck*, as plotted in Fig. 6, overlotted on constraints obtained from realizations of a lensed- Λ CDM+noise+dust model with dust power similar to that favored by the real data ($A_d = 3.6 \mu\text{K}^2$). Half of the r curves peak at zero as expected.

FIG. 11. Constraints obtained when adding dust realizations from the *Planck* Sky Model version 1.7.8 to the base lensed- Λ CDM+noise simulations. (Curves for 139 regions with peak $A_d < 20 \mu\text{K}^2$ are plotted). We see that the results for r are unbiased in the presence of dust realizations which do not necessarily follow the $\ell^{-0.42}$ power law or have Gaussian fluctuations about it.

as the level of A_d increases, and we should therefore not be surprised if the fraction of realizations peaking at a value higher than the real data is increased compared to the simulations with mean $A_d = 3.6 \mu\text{K}^2$. However we still expect that on average 50% will peak above zero and approximately 8% will have an L_0/L_{peak} ratio less than the 0.38 observed in the real data. In fact we find 57% and 7%, respectively, consistent with the expected values. There is one realization which has a nominal (false) detection of non-zero r of 3.3σ , although this turns out to also have one of the lowest L_0/L_{peak} ratios in the Gaussian simulations shown in Fig. 10 (with which it shares the CMB and noise components), so this is apparently just a relatively unlikely fluctuation.

FIG. 12. *Upper*: BB spectrum of the BICEP2/*Keck* maps before and after subtraction of the dust contribution, estimated from the cross-spectrum with *Planck* 353 GHz. The error bars are the standard deviations of simulations, which, in the latter case, have been scaled and combined in the same way. The inner error bars are from lensed- Λ CDM+noise simulations as in the previous plots, while the outer error bars are from the lensed- Λ CDM+noise+dust simulations. *Lower*: constraint on r derived from the cleaned spectrum compared to the fiducial analysis shown in Fig. 6.

B. Subtraction of scaled spectra

As previously mentioned, the modified blackbody model predicts that dust emission is 4% as bright in the BICEP2 band as it is in the *Planck* 353 GHz band. Therefore, taking the auto- and cross-spectra of the combined BICEP2/*Keck* maps and the *Planck* 353 GHz maps, as shown in the bottom row of Fig. 2, and evaluating $(BK \times BK - \alpha BK \times P)/(1 - \alpha)$, at $\alpha = \alpha_{\text{fid}}$ cleans out the dust contribution (where $\alpha_{\text{fid}} = 0.04$). The upper panel of Fig. 12 shows the result.

As an alternative to the full likelihood analysis presented in Sec. III B, we can instead work with the differenced spectra from above, a method we denote the “cleaning” approach. If α_{fid} were the true value, the ex-

pectation value of this combination over CMB and noise would have no dust contribution. However, dust would still contribute to its variance, but only through its 2-point function. In practice, we do not know α perfectly, and this uncertainty needs to be accounted for in a likelihood constructed from the differenced spectra. Our approach is to treat the differenced spectra as a form of data compression, and to compute the expectation value as a function of r , A_d , and β_d at each point in parameter space (the dust dependence enters for $\alpha(\beta_d) \neq \alpha_{\text{fid}}$). We use the method of Ref. [42], with a fiducial covariance matrix, to build a likelihood for the difference spectra, and marginalize over A_d and β_d , and hence α , adopting the prior $\beta_d = 1.59 \pm 0.11$. This alternative likelihood has the advantage of being less sensitive to non-Gaussianity of the dust, since only the 2-point function of the dust affects the covariance of the differenced spectra close to α_{fid} , while the full analysis may, in principle, be affected by the non-Gaussianity of the dust through 4-point contributions to power spectra covariances. This cleaning approach does, however, ignore the (small amount of) additional information available at other frequencies. The lower panel of Fig. 12 compares the result to the fiducial analysis with the full multi-spectra likelihood. It is clear from the widths of the likelihood curves that compressing the spectra to form the cleaned difference results in very little loss of information on r . The difference in peak values arises from the different data treatments and is consistent with the scatter seen across simulations. Finally, we note that one could also form a combination $(\text{BK} \times \text{BK} - 2\alpha \text{BK} \times \text{P} + \alpha^2 \text{P} \times \text{P}) / (1 - \alpha)^2$ in which dust does not enter at all for $\alpha = \alpha_{\text{fid}}$. However, the variance of this combination of spectra is large due to the *Planck* noise levels, and likelihoods built from this combination are considerably less constraining.

V. POSSIBLE CAUSES OF DECORRELATION

Any systematic error that suppresses the $\text{BK150} \times \text{P353}$ cross-frequency spectrum with respect to the $\text{BK150} \times \text{BK150}$ and $\text{P353} \times \text{P353}$ single-frequency spectra would cause a systematic upward bias on the r constraint. Here we investigate a couple of possibilities.

A. Spatially varying dust frequency spectrum

If the frequency dependence of polarized dust emission varied from place to place on the sky, it would cause the 150 GHz and 353 GHz dust sky patterns to decorrelate and suppress the $\text{BK150} \times \text{P353}$ cross-spectrum. The assumption made so far in this paper is that such decorrelation is negligible. In fact PIP-XXX implicitly tests for such variation in their Figure 6, where the *Planck* single- and cross-frequency spectra are compared to the modified blackbody model (with the cross-frequency spectra plotted at the geometric mean of their respective frequen-

cies). This plot is for an average over a large region of low foreground sky (24%); however, note that if there were spatial variation of the spectral behavior anywhere in this region it would cause suppression of the single-frequency spectra with respect to the cross-frequency spectra.

PIP-XXX also tests explicitly for evidence of decorrelation of the dust pattern across frequencies. Their figure E.1 shows the results for large and small sky patches. The signal-to-noise ratio is low in clean regions, but no evidence of decorrelation is found.

As a further check, we artificially suppress the amplitude of the $\text{BK150} \times \text{P353}$ spectra in the Gaussian dust-only simulations (see Sec. IV A) by a conservative 10% (PIP-XXX sets a 7% upper limit). We find that the maximum likelihood value for r shifts up by an average of 0.018, while A_d shifts down by an average of $0.43 \mu\text{K}^2$, with the size of the shift proportional to the magnitude of the dust power in each given realization. This behavior is readily understandable—since the $\text{BK150} \times \text{BK150}$ and $\text{BK150} \times \text{P353}$ spectra dominate the statistical weight, a decrease of the latter is interpreted as a reduction in dust power, which is compensated by an increase in r . The bias on r will be linearly related to the assumed decorrelation factor.

B. Calibration, analysis etc.

Figure 3 shows that the EE spectrum $\text{BK150} \times \text{BK150}$ is extremely similar to that for $\text{BK150} \times \text{P143}$. We can compare such spectra to set limits on possible decorrelation between the *BICEP2/Keck* and *Planck* maps arising from any instrumental or analysis related effect, including differential pointing, polarization angle mis-characterization, etc. Taking the ratio of $\text{BK150} \times \text{P143}$ to the geometric mean of $\text{BK150} \times \text{BK150}$ and $\text{P143H1} \times \text{P143H2}$, we find that for TT the decorrelation is approximately 0.1%. For EE the signal-to-noise ratio is lower, but decorrelation is limited to below 2%, and consistent with zero when compared to the fluctuation of signal+noise simulations.

VI. CONCLUSIONS

BK-I reported a highly significant detection of B -mode polarization, at 150 GHz, in excess of the lensed- Λ CDM expectation over the range $30 < \ell < 150$. This excess has been confirmed by additional data on the same field from the successor experiment *Keck Array*. PIP-XXX found that the level of dust power in a field centered on the *BICEP2/Keck* region (but somewhat larger than it) is of the same magnitude as the reported excess, but noted that, “the present uncertainties are large,” and that a joint analysis was required.

In this paper we have performed this joint analysis, using the combined *BICEP2/Keck* maps. Cross-correlating these maps against all of the polarized frequency bands

of *Planck* we find a highly significant B -mode detection only in the cross spectrum with 353 GHz. We emphasize that this 150×353 GHz cross-spectrum has a much higher signal-to-noise ratio than the 353 GHz single-frequency spectrum that PIP-XXX analyzed.

We have analyzed the data using a multi-frequency, multi-component fit. In this fit it is necessary to impose a strong prior on the variation of the brightness of the dust emission with observing frequency, since the available data are unable to constrain this alone, due to the relatively low signal-to-noise ratio in B -mode polarization at 353 GHz. However PIP-XXX clearly shows that the frequency spectrum of dust emission is quite uniform across the entire high latitude sky—a necessary condition for the type of analysis employed here.

We have shown that the final constraint on the tensor-to-scalar ratio r is very stable when varying the frequency bands used, as well as the model priors. The result does differ when using the BICEP2 and *Keck Array* data alone rather than in combination, but the difference is compatible with noise fluctuation. Expanding the model to include synchrotron emission, while also including lower *Planck* frequencies, does not change the result.

Allowing the amplitude of lensing to be free, we obtain $A_L = 1.13 \pm 0.18$, with a significance of detection of 7.0σ . This is the most significant direct detection to-date of lensing in B -mode polarization, even compared to experiments with higher angular resolution. The POLAR-BEAR experiment has reported a detection of B -mode lensing on smaller angular scales ($500 < \ell < 2100$), rejecting the $A_L = 0$ hypothesis at 97.2% confidence [47]. Additionally, ACT [48] and SPT [49] have reported lensing detections in polarization in cross-correlation with some other tracer of the dark matter distribution on the sky.

We have validated the main likelihood analysis on simulations of a dust-only model and performed a simple subtraction of scaled spectra, which approximates a map-based dust cleaning (obtaining an r constraint curve that peaks somewhat lower). Finally we investigated the possibility of astrophysical or instrumental decorrelation of the sky patterns between experiments or frequencies and find no evidence for relevant bias.

The final result is expressed as a likelihood curve for r , and yields an upper limit $r < 0.12$ at 95% confidence. The median limit in the lensed- Λ CDM+noise+dust simulations is $r < 0.075$. It is interesting to compare this latter to dust-free simulations using only BICEP2/*Keck* where the median limit is $r < 0.03$ —the difference represents the limitation due to noise in the *Planck* maps, when marginalizing over dust. The r constraint curve peaks at $r = 0.05$ but disfavors zero only by a factor of 2.5. This is expected by chance 8% of the time, as confirmed in simulations of a dust-only model. We emphasize that this significance is too low to be interpreted as a detection of primordial B -modes. Transforming the *Planck* temperature-only 95% confidence limit of $r_{0.002} < 0.11$ [3] to the pivot scale used in this paper

yields $r_{0.05} < 0.12$ compatible with the present result.

A COSMOMC module containing the EE and BB band-powers for all cross-spectra between the combined BICEP2/*Keck* maps and all of the frequencies of *Planck* is available for download at <http://wheretogetdata>.

In order to further constrain or detect IGW, additional data are required. The *Planck* Collaboration may be able to make progress alone using the large angular scale “reionization bump,” if systematics can be appropriately controlled [50]. To take small patch “recombination bump” studies of the type pursued here to the next level, data with signal-to-noise comparable to that achieved by BICEP2/*Keck* at 150 GHz are required at more than one frequency. Figure 13 summarizes the situation. The BICEP2/*Keck* noise is much lower in the BICEP2/*Keck* field than the *Planck* noise. However, since dust emission is dramatically brighter at 353 GHz, it is detected in the cross-spectrum between BICEP2/*Keck* and *Planck* 353 GHz. Synchrotron is not detected and the crossover frequency with dust is $\lesssim 100$ GHz. *Planck*’s PR2 data release [51] shows that for the cleanest 73% of the sky, at $40'$ scales, the polarized foreground minimum is at ~ 80 – 90 GHz. During the 2014 season, two of the *Keck Array* receivers observed in the 95 GHz band and these data are under active analysis. BICEP3 will add substantial additional sensitivity at 95 GHz in the 2015, and especially 2016, seasons. Meanwhile many other ground-based and sub-orbital experiments are making measurements at a variety of frequencies and sky coverage fractions.
